A. Hardware

- A.1) 16 MHz.** The frequency of the clock was found to be 16 MHz from the datasheet.
- A.2) 16/20 MHz.** Data differs between different datasheets I checked.
- A.3) Power.** Higher voltages are required to run at higher frequencies c.f. Fig 2a, presumably due to loads causing reduction in voltage and it becoming harder to distinguish between low and high. At the same time, the current required increases as well (Fig. 2b). Thus, the net increase in power will limit the frequency at which we can drive the chip due to thermal as well as electric constraints. Thermal should set in first. If you were able to provide external cooling say with a fan, electrical limitations would take over soon.
- A.4) Setup done.**

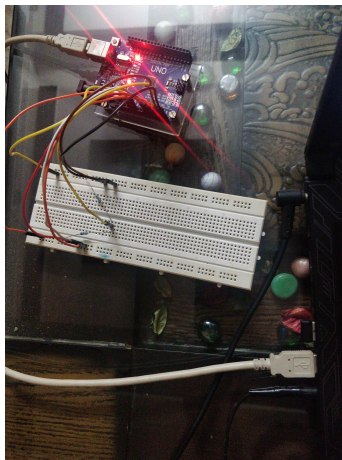

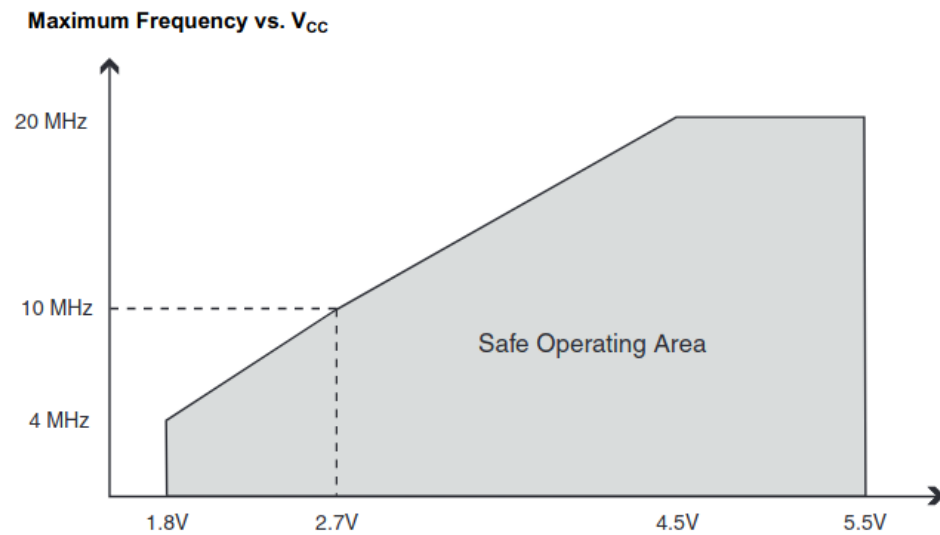

Figure 1: Arduino connected to laptop

(a) $V - f$

Active Supply Current versus Frequency

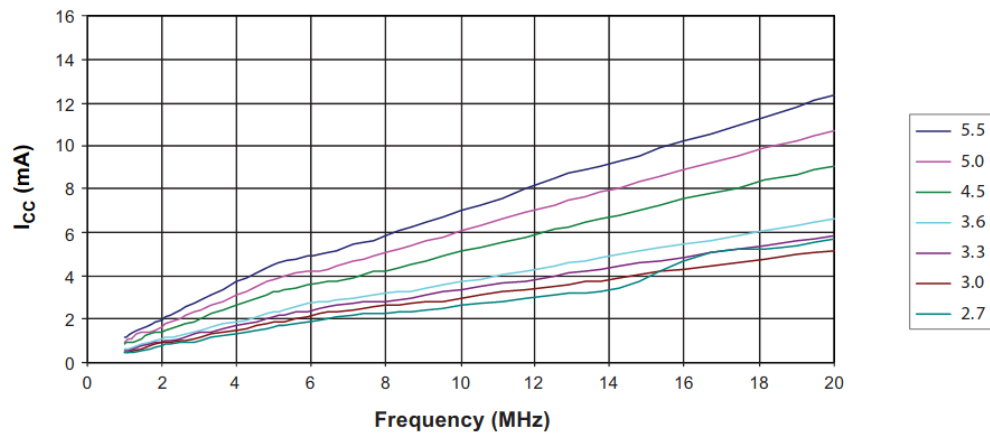

(b) $f - I$

Figure 2: Graphs for electric constraints with frequency
 Taken from <https://www.microchip.com/wwwproducts/en/ATmega328p>

B. Digital I/O

B.1) With access to a DSO, the time taken to execute a digital write may be obtained using a program like this:

```

1  void setup(){
2      pinMode(LED_BUILTIN, OUTPUT);
3  }
4
5  void loop(){
6      digitalWrite(LED_BUILTIN, LOW);
7      digitalWrite(LED_BUILTIN, HIGH);
8  }
9

```

The DSO probe would be connected to pin 13, corresponding to the LED, and ground. The time taken for the instruction will be half of the time period of the obtained (presumably square) wave.

B.2) I put the function to be tested in the loop() section (see Appendix) and then monitored the output using a C++ program with the serial output pipelined into it. The C++ program was designed to count instances of an arbitrary provided string and time it with a high resolution clock.

The following results were obtained by timing the given program:

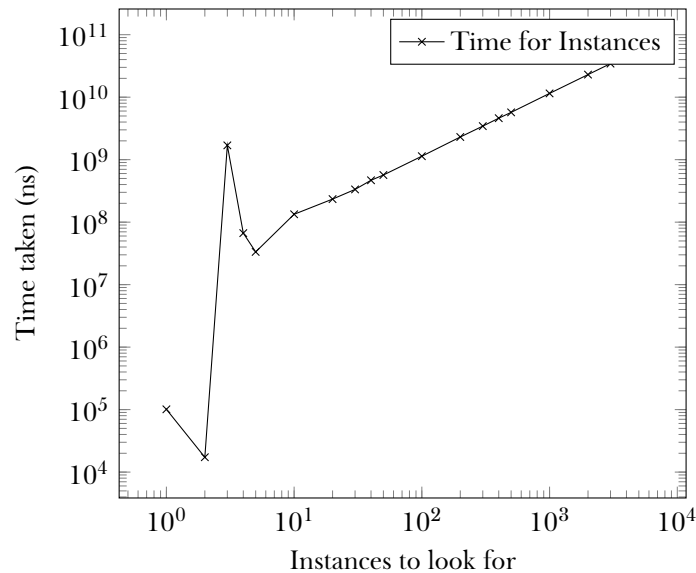

Figure 3: Time taken to receive instances of "01Game Over"

Looking at the figure, the first few points are quite erratic, possibly due to many small factors interacting, such as transmission delay, serial polling delay, etc. The data very quickly settles into a linear plot, which was used to determine a best fit line of the form

$$y = mx + c$$

with obtained values,

$$m = 1.148 \times 10^7 \text{ ns}$$

$$c = 3.907 \times 10^5 \text{ ns}$$

using a least-squares fit.

Thus, the average time per function run was 1.148×10^7 ns, i.e. **11.48 ms**.

It is also worth noting the obtained value for c . There seems to be a sizable constant delay for each instance run. This may be attributed to the overhead of the timing methodology, the buffer as well as the timing program itself. It being a couple orders of magnitude smaller than the actual slope ensures that our testing methodology was appropriate and did not skew the results too much.

Note — data for less than 10 instances was not included for the best fit.

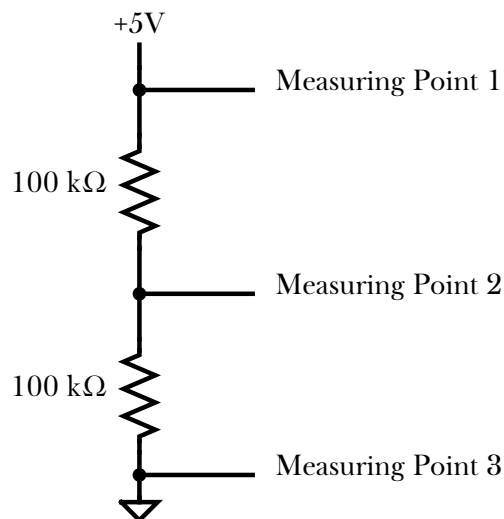

Actual data values and testing details may be found in the Appendix.

C. Analog Input

C.1) Quite mixed with the next part, so combined answer in **C.2)**

C.2) The analog ports A0-A5 were connected to a voltage divider between 5V and GND taken from the Uno itself as the circuit in Fig 4a and the program as in 4b. The actual setup was as already included in Fig 1.

The wires were moved between the three measuring points during the course of the execution to collect data.

(a) Voltage divider circuit

```
1 void setup(){
2     Serial.begin(9600);
3 }
4
5 void loop(){
6     Serial.print("\nValues : ");
7     for(int port = A0; port <= A5; port++){
8         Serial.print(analogRead(port));
9         Serial.print(' ');
10    }
11    delay(3000);
12 }
13
```

(b) Code used for measuring analog inputs

Figure 4: Setup for the analog input measuring

The output received was as following, ordered as A0 to A5.

```
▲ sankalp ~ tail -f /dev/ttyUSB0
```

```
Values : 1023 1023 1023 511 0 0  
Values : 1023 1023 1023 512 0 0  
Values : 1023 1023 1023 769 0 0  
Values : 1023 1023 1023 1023 0 72  
Values : 1023 1023 1023 1023 512 512  
Values : 1023 1023 1022 1023 512 512  
Values : 1023 1023 1023 1023 512 512
```

It was interesting to see the values in the middle as I managed to read them while moving wires around. Not sure if this is dangerous (hopefully not!) but it was nice to see the input values changing, presumably due to a buffering circuit to smooth over the input in some way?

Appendix

Arduino

The code uploaded to the Arduino for testing. The function `test()` is to make the testing more modular by changing the timed function once, and added multiple times as required without overhead, since the `inline` keyword ensures resolution of calls at compile-time. The functionality was, however not utilized here in the end.

```
1  /*
2  Lab 1
3  Arduino Basics
4  */
5
6  // variables
7
8  // functions
9  inline void test();
10
11 void setup(){
12     Serial.begin(9600);
13     pinMode(LED_BUILTIN, OUTPUT);
14 }
15
16 void loop(){
17     test();
18 }
19
20 inline void test(){
21     digitalWrite(LED_BUILTIN, LOW);
22     Serial.print('0');
23     digitalWrite(LED_BUILTIN, HIGH);
24     Serial.print('1');
25     Serial.print("Game Over");
26 }
```

C++ Timer

The code used to time the output at a lower level than via the IDE. The IDE seems to be made fairly efficiently as the results were close. The output is buffered using the UNIX `tail` utility, with the `-f` indicating follow, checking the stream at intervals provided by `-s`, or `sleep`, used as `1μs` here for reasonable accuracy. The output buffer generated by `tail` is piped into the C++ program as `stdin` to be read the same as any user input. The tests were performed with (an unnecessary) nanosecond accuracy using a high resolution clock provided by `std::chrono`.

```
1  #include <iostream>
2  #include <chrono>
3  #include <vector>
4
5  std::vector<int> checks{1}; // add an empty check to account for initial setup delay
6  const char * test_string = "01Game Over"; // arbitrary string to look for
7
8  int main(){
9
10     char c = (char) 0;
11     int pos_test = 0; // position in test string during traversal
12     int count = 0; // number of test strings seen
```

```
13
14 // construct the checks vector as
15 // 1, 2, 3, 4, 5,
16 // 10, 20, 30, 40, 50, ....
17 // 10000, 20000, 30000, 40000, 50000
18 int i = 1;
19 for(int j = 1; j < 6; j++){
20     checks.emplace_back(i*j);
21
22     if(j == 5 && i < 10000){
23         j = 0;
24         i *= 10;
25     }
26 }
27
28
29 auto curr_time = std::chrono::high_resolution_clock::now();
30 auto last_time = curr_time;
31
32 while(!checks.empty()){
33     if(count == checks[0]){
34         // log a hit
35         curr_time = std::chrono::high_resolution_clock::now();
36         std::chrono::duration<double, std::nano> time_taken = curr_time - last_time;
37         last_time = curr_time;
38         std::cout << "Count " << count
39                 << " : Time " << time_taken.count()
40                 << " ns" << std::endl;
41
42         // remove this check
43         checks.erase(checks.begin());
44         // reset
45         count = 0;
46     }
47
48
49     // have we found the entire string?
50     if(test_string[pos_test] == (char) 0){
51         count++;
52         pos_test = 0;
53         continue;
54     }
55
56     // get the next character
57     c = std::cin.get();
58
59     if(c == test_string[pos_test]){
60         pos_test++;
61     }
62
63 }
64
65 return 0;
66 }
```

Results

The command used to obtain the output as well as the explicit output. The first "1 count" may be ignored,

as its time is due to the `curr_time` being set outside of the loop. The library `std::chrono` has been previously measured to be fast enough to only cause delays of the order of 10ns, so it is not a rate limiter here. The tests were stopped at 5k for this case, since they would take a bit long for more, and don't add much information.

```
▲ sankalp .../lab1 tail -f /dev/ttyUSB0 -s 0.000001 | ./arduino-timer.out
```
